A Bose-Einstein condensate is an intriguing state of matter where extensive collective coherence leads to macroscopic quantum phenomena. It has now been demonstrated using a thin plastic film at room temperature. This provides a new, simple route to experimentally study many-body quantum physics and opens the door for device applications.
n the 1920s Satyendranath Bose and Albert Einstein predicted the existence of a new state of matter near the absolute zero temperature. At this low temperature, particles do not behave like point-like billiard balls anymore but acquire significant spatial extension as their de Broglie wavelength increases with decreasing temperature. At sufficiently high density, the wavefunctions of particles whose behaviour in the ensemble follows the so-called Bose-Einstein statistics, start to overlap and accumulate in the lowest energy state. Thereby they lose their individual character and instead form a macroscopic “super-particle”, the Bose-Einstein condensate. 

Looking into nature’s quantum kitchen

While it was soon realized that there is an intricate relationship with the phenomena of superfluidity in liquid helium and superconductivity, it took physicists 70 years to create such a state of matter in the laboratory. In 1995, Eric A. Cornell and Carl E. Wieman from JILA in Boulder [1], and Wolfgang Ketterle from MIT in Boston [2] achieved Bose-Einstein condensation in dilute alkali gases at temperatures below a few micro Kelvin, for which they were later awarded the Nobel prize. This breakthrough paved the way for an ongoing, long series of fundamental studies of genuine quantum effects and phases, exploiting the unprecedented possibilities to control, manipulate and investigate this special quantum many-body state. A truly fascinating and appealing aspect of all these experiments is that one can literally really see quantum mechanics “at work”.

Shortly after the first BEC, Atac Imamoğlu and co-workers predicted that similar phenomena should be observable also in solid state systems [3]. Here the condensing bosons would be quasi-particles (so-called polaritons) created by strong coupling between bound electron-hole pairs (excitons) and photons in an optical microcavity (see BOX). In contrast to alkali atoms, their number is not conserved as they can readily be created by pumping with a laser and destroyed by recombination of electron-hole pairs or photons leaking out of the cavity. Therefore it is different from Bose and Einstein’s original model because the driven and dissipative nature of polaritons intrinsically prohibits thermal equilibrium with the environment. A compelling advantage, however, is that the effective mass of these polaritons is on the order of $10^{10}$ times less than the mass of alkali atoms, which boosts the critical temperature for BEC above room temperature. Furthermore, photons leaking out from the cavity transport all the necessary information about the polariton state to the outside world where they can easily be measured with a spectrograph or imaged by a camera.

From dilute gases at a few micro Kelvin to semiconductors crystals at room temperature

In 2006, the groups of Benoît Deveaud-Plédran in Lausanne and Le Si Dang in Grenoble jointly demonstrated the first polariton BEC in CdTe quantum wells at -268°C [4]. In the following years, other groups reported polariton BECs at room temperature, using GaN or ZnO structures. The delicate and defect-free growth of these semiconductor crystals and quantum wells is very challenging and only mastered by a handful of laboratories world-wide. However, the quest for materials with relaxed requirements on the quality and better suitability for application in devices is opposed by the fundamental difficulty to realize a very ordered phase such as the BEC in disordered materials.

Very recently, our group at IBM Research – Zurich used an amorphous 35 nm-thin polymer film embedded in an optical microcavity to achieve polariton BEC [5] (see Intro Illustration). The special luminescent polymer, which was developed about 20 years ago at the Max-Planck Institute for Polymer Research in Mainz for organic light emitting diodes (OLED), features a rigid backbone to reduce intrinsic disorder and enhance its optical properties.

Can something as ordered as a Bose-Einstein condensate be created in something as disordered as a polymer film?

By exciting the polymer film with picosecond laser pulses at a wavelength of 400 nm, the transition from a normal phase to BEC shows up in the polariton dispersion (Fig. 1). The spectrum and angular distribution of the light coming from the microcavity allows to directly map out the dispersion relation and the occupation of the polariton states as a function of energy and momentum. At low pump intensity, the parabolic shape of the polariton dispersion is observed, where the intensity distribution reflects a Boltzmann distribution in energy and momentum – as expected for a thermalized ensemble of polaritons. When the intensity of the pump laser and therefore the polariton density is increased, suddenly a new peak appears which is much narrower in energy and momentum than the parabolic polariton dispersion. This is a key
signature of the polariton BEC. Owing to the stimulated scattering mechanism responsible for the population of the BEC state, its intensity grows strongly super-linear with excitation power. It is slightly shifted to higher energy compared to the polariton parabola because of the repulsive Coulomb interaction in the dense ensemble of electron-hole pairs.

The most striking feature of a BEC is the emergence of long-range phase coherence where the wavefunctions of the condensing bosons are synchronized over macroscopic distances. This can be directly probed by sending the photons from the microcavity through a Michelson interferometer and recombining the light from the two interferometer arms on a camera. If the polaritons were coherent, they should interfere constructively and destructively and therefore form a fringe pattern. We observe such interference patterns over almost the whole pumped area which is several tens of micrometers in diameter (Fig. 2). Furthermore, certain characteristic patterns such as fork-like structures are indicative of the presence of vortex-like excitations in the condensate. As the total duration of this pulsed-driven BEC is currently on the order of a few picoseconds only, the observations are dominated by the “birth phase” of the condensate where vortices are expected to be quite ubiquitous [6]. Actually, this is a consequence of the so-called Kibble-Zurek mechanism that is a general feature of sudden phase transitions, and which was also at play in the formation of matter in the early universe.

Nearly two decades after the first atomic gas condensate just above absolute zero, we now have arrived at (non-equilibrium) BEC at room temperature in a plastic film. But apart from beautiful textbook-like quantum mechanical experiments, what is it good for in terms of applications? Most recently, atomic gas BECs have been used for “quantum simulations” of other physical systems, which are hardly experimentally accessible or even not theoretically tractable [7]. For the solid-state polariton BEC, opto-electronic applications come within reach. Here the promise is to use the coherent laser-like light from the polariton BEC as micro-laser that does not require the energy-intensive creation of population inversion in the gain medium like in conventional lasers. The first electrically pumped polariton laser based on semiconductor quantum wells has just been demonstrated at a few degrees above absolute zero [8]. With the polymer-based BEC, however, electrical driving will be much more difficult, given the low charge mobility in the material, and will certainly require another quantum leap. Nevertheless, even optically driven polariton BECs are expected to provide deeper insight into fascinating quantum effects, especially simulating non-equilibrium phenomena on very fast timescales. And this has just become radically easier than ever before, something that Bose and Einstein probably would not have dreamed of almost 90 years ago.

BOX: EXCITON-POLARITONS

The optical activity of semiconductors, organics and most other materials originates from electron-hole pairs that can be formed by absorption of light or electrical excitation and can emit light by recombination. In the simplest approximation, this can be described as a two-level system with ground state (no exciton) and excited state (exciton has been formed). Placing such a material into a resonator that is tuned to the transition energy between the two states gives rise to new eigenstates of the coupled system, given that the interaction rate $\Omega$ between the cavity photon and the exciton is larger than the spontaneous emission rate $\gamma$ and the leakage rate $\kappa$ from the cavity. The resulting quasi-particles composed of half-exciton and half-photon are called exciton-polaritons and inherit the bosonic character from their constituents.
About the authors

Thilo Stöferle received his PhD from ETH Zurich in 2005 for the investigation of Bose-Einstein condensates and degenerate Fermi gases in optical lattices. In 2006 he joined IBM Research – Zurich where he is working on highly efficient nanoscale components for integrated optical communication.

Rainer F. Mahrt received his PhD in 1991 and his habilitation in 1997 in Physical Chemistry from Marburg University. He was appointed a group-leader position at the Max-Planck Institute in 1999. In 2001 he joined IBM Research – Zurich. Current research interests are optics of organic/inorganic hybrid systems in photonic band gap structures.

About “scientific consensus on climate change”

It has been with great astonishment that I found published on the 44/6 issue of EPN, a journal of a scientific Society, the article “Scientific consensus on climate change”.

Climate change is a complex physical phenomenon or better a set of physical phenomena that are being scientifically studied, including their possible anthropic causes. It is also a highly politically sensitive issue. As scientists we should, I think, keep the two aspects well separated.

On the contrary, the article published by EPN pretends to prove the existence of human-caused global warming, “by consensus”. The point here is not whether the theory of human caused global warming is true or not, but the means that is used to prove that. Consensus rather than experiment. “Consensus can be measured; if it is large enough it proofs the theory”. This is an extremely dangerous behaviour. Consensus is the instrument of democracy. Science is not democracy; it rests on the Galilei scientific method. Abandoning that will bring us back to the Middle Ages. It is astonishing to find this view in a Journal of a scientific society.

I would like to ask you to publish my letter.

Thanks for your attention.

The Editor responds

Europhysics News offers its readers a forum to publish articles which are interesting to a wide readership and which satisfy accepted scientific standards. The Feature by John Cook meets both criteria. Prof. Bettini claims that the author uses consensus to prove the existence of human-caused global warming, but this is not the case. What the author does show is that there is a much larger consensus among climate scientists than the public thinks. The quote “Consensus can be measured; if it is large enough it proofs the theory” does not appear in the article.
